Abstract
Measuring wind offshore in deep water depths will be a future challenge. Where the seabed installation of foundations for fixed met masts is impossible, even the mooring of floating systems are more complicated. Ship-lidar systems are an alternative solution for a number of different applications.

In this poster we describe two motion-correction methods for motion-influenced lidar measurements. The ship-lidar system will be presented as well as the first measurements carried out as part of the EERA-DTOC project. Therefore a verification of one correction algorithm will be shown as well as first results from wake measurements behind the Alpha Ventus offshore wind farm.

Verification of correction algorithm
For the first analysis, the simplified correction algorithm was applied on the measured data. Figure 5 shows results of uncorrected, yaw corrected (rotated) and fully corrected data for one-minute-mean values for the 5th of October 2013.

Wake measurements
First wake measurements were performed with ship tracks perpendicular to the wakes, see figure 8. Results show distinct wakes for a distance of approx. 150 m, see figure 7. These wakes can be identified by decreased wind speeds and increased turbulence.

Conclusions
First ship-based lidar measurements next to met masts FINO1 show good correlations for wind speed and direction using the simplified correction. Nevertheless it is assumed that the complete motion correction will improve the data.

Measuring set-up
The ship-lidar system comprises a Leosphere WindCube V2 device, different motion-sensors (AHRS, satellite compass), a computer for data acquisition as well as equipment for power supply and wireless communication. The system is combined in a frame in order to ensure a fixed geometry, compare [1].

For the presented measurements, the system was installed on the offshore support vessel LEV TAIFUN with a length of 41.45 m. The system was located approx. 7 m above the point of rotation, whereas the roll frequency is close to f=5 s with extreme roll angles up to 20°

Motion correction algorithms
Wind-lidar measurements using line of sight (LoS) measurements in different beam orientations are solved under the assumption of homogeneity as well as constant wind velocity on each altitude, using a system of linear equations (SLE):

\[ \begin{align*}
\sigma_x(t_1) & \quad \sigma_x(t_2) & \quad (h) \\
\sigma_y(t_1) & \quad \sigma_y(t_2) & \quad \vdots
\end{align*} = \begin{align*}
\begin{bmatrix}
\sigma_x(t_1) \\
\sigma_y(t_1)
\end{bmatrix}
\begin{bmatrix}
\gamma_{x}(t_1,h) \\
\gamma_{y}(t_1,h)
\end{bmatrix}
\end{align*}
\]

In general, these measurements can be influenced by translatory and rotatory motions, that can be considered by modifying the SLE to

\[ \sigma_{\text{fin}} \cdot \begin{bmatrix}
\sigma_x(t_1) \\
\sigma_y(t_1)
\end{bmatrix} = \begin{bmatrix}
\gamma_{x}(t_1,h) \\
\gamma_{y}(t_1,h)
\end{bmatrix} \]

Under the assumption of constant orientation and motion during the time period covered by the system of SLE, a simplified motion correction can be applied on the resulting wind vector from the SLE.

\[ \sigma_{\text{fin}} \cdot \left[ \begin{array}{c}
\sigma_x(t_1) \\
\sigma_y(t_1)
\end{array} \right] = \begin{array}{c}
\gamma_{x}(t_1,h) \\
\gamma_{y}(t_1,h)
\end{array} \]

Especially periodical tilting motions in the frequency range of the lidar measurement frequency, combined with additional translatory motion due to the distance from lidar to center of rotation can lead to beating effects that are not considered by the simplified motion correction.

Floating lidar corrections algorithms were studied in [2] and [3].

Measurement campaigns
For the EU FP7-funded EERA-DTOC project, two measurement campaigns were performed from 27-31 August 2013 and 04-08 October 2013 comprising approx. 7.5 days in proximity to Alpha Ventus wind farm.

Goal of the measurement was the survey of wind farm wakes in different distances. In order to verify the measurement principle, data was also acquired in free inflow in proximity to FINO1.
